Aerodynamic drag G profile Unsmoothed position data

20. ABSTRACT (Continue on reverse side if necessary and identify by block number)

A procedure is described for determining the aerodynamic drag and G profile of a missile using unsmoothed observed position data. The procedure uses numerical integration in computing trajectory data that simulates the observed data. An iterative process is used to obtain a reasonable match between the computed and observed trajectory data. The aerodynamic drag used in computing the trajectory that matches the observed data is a good estimate of the drag of the missile. The G profile is included in the computation. An example is given

FOREWORD

The purpose of this report is to describe a procedure for determining the aerodynamic drag and G profile of a missile. While this procedure has been used to some extent for several decades, it has never been adequately documented.

This work was performed in the Exterior Ballistics Branch under AIRTASK No. A541-5413/165-4/154100013.

This report was reviewed by D. R. Daniel, Head, Exterior Ballistics Branch, and C. W. Duke, Jr., Head, Space and Surface Systems Division.

INTRODUCTION

In the decade following World War II, our efforts to develop new missiles and increase our knowledge of exterior ballistics were greatly expanded. Two things that made a large contribution to this effort were the introduction of phototheodolites to track missiles released from aircraft and electronic computers to analyze the test data.

In the very early stages, the Gâvre drag function was used almost exclusively in a trajectory model to simulate the observed flight data. The drag function was scaled for each store in order to obtain a match between the computed and observed ranges. As the state of the art improved, different drag functions were determined from wind tunnel tests and spark range firings for many of the stores in the Navy stockpile. Refinements were made to these drag functions by comparing observed and computed spatial coordinates at intermediate points in the trajectories as well as the terminal points. Smoothing techniques also became popular for determining the drag function of a missile from observed spatial coordinates since large quantities of test data could be processed quite rapidly with a minimum of labor involved. These smoothing techniques could also be used very effectively, in many instances, to reduce the noise level in the test data. Largely due to their popularity, smoothing techniques have been accepted as the "norm" for establishing aerodynamic coefficients and G schedules using observed position data.

There are a variety of procedures available for determining the aerodynamic drag and G schedule of a missile that involve the use of smoothing techniques. Perhaps the most popular method is a least-squares technique involving the use of a polynomial fit to a moving arc that is evaluated at the midpoint. Another popular method involves digital filters, which may also be applied to trajectory data. Either one of these methods, which involve the use of smoothing techniques, will

provide estimates of velocity and acceleration which are required in computing aerodynamic drag and G schedule. Some of the problems that are encountered with smoothing techniques are described in Appendix A.

While smoothing routines may frequently be used very effectively to reduce the noise in data, they will also reduce large perturbations that may belong in the data. Trajectory data obtained from tracking missiles that have retardation devices activated in flight are extremely difficult to smooth without sacrificing a portion of the peaks that belong in the data.

The procedure described in this report uses a different approach to compute the aerodynamic drag and G schedule of a missile. A particle model is used to compute trajectories that simulate the observed position data. The model uses three translational equations of motion, 1 which provide for motion along three orthogonal axes. The equations are solved using a fourth-order Runga-Kutta method of numerical integration. The rectangular coordinate system, which is illustrated in Figure 1, is described as follows.

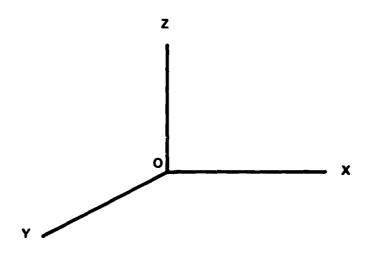

FIGURE 1. RECTANGULAR COORDINATE SYSTEM

The XY plane is perpendicular to the plumb line passing through the range origin, O, and tangent to the mean-sea-level Clarke spheroid of 1866 at the origin. The X axis is positive in the direction of true north, the positive Y axis is 90° clockwise from the positive X axis, and the Z axis is positive upward.

Trajectories are computed with this model, and the results are compared to the unsmoothed position data obtained by tracking the missile in flight. Adjustments are made to the ballistic parameters used in the computation until the differences in computed and observed position data are within the accuracy of the observed data or the differences are not significant. The aerodynamic drag used in computing the trajectory that matches the observed data provides a good estimate of the aerodynamic drag of the missile. The G schedule is included in the computation. To demonstrate the procedure, it was applied to a sample trajectory of the B61 Mod 0 bomb with the parachute deployed in the retarded laydown mode. A comparison of the results obtained with the procedure and two smoothing techniques is presented in the RESULTS section.

PROCEDURE

The method presented in this report for determining the aerodynamic drag and G schedule of a missile using unsmoothed position data may be described in the following manner.

A trajectory is computed with the model outlined in the previous section that simulates the actual conditions of a missile in flight as nearly as possible. A reference weight and diameter of the missile, observed meteorological data, local gravity, and observed event times are used in the computation. The best estimate of initial position, velocity, event times, and aerodynamic drag is used initially. Adjustments to the initial position and velocity are made if necessary to improve the match for a brief period after release. Based on the differences for the remainder of the trajectory, adjustments are made if necessary to the aerodynamic drag and event times. The process is repeated until a match between the observed and computed position data is obtained that is within the accuracy of the observed data or the differences are not significant. The difference between the arc lengths of the observed and computed trajectories are frequently used as a criteria for making final adjustments to the aerodynamic drag. In some situations it may be necessary to concentrate on a segment of a trajectory before attempting to match the next segment or remaining portion.

The procedure was applied to trajectory data for an early version of the B61 Mod 0 bomb deployed in the retarded laydown mode where the parachute failed to open as designed. The trajectory data were provided by Sandia National Laboratories. Meteorological data are tabulated in Appendix B, which were obtained by releasing a radiosonde 4 min prior to the time the store was released.

The actual weight of 715 lb and a reference diameter of 13.5406 in. were used in the computation. A bomb with this diameter has a cross-section area of 1 ft²; consequently, the CD represents the CDS. The aerodynamic drag of a parachute is stated frequently in terms of CDS. The event times used in the computation were line stretch at 0.75 sec after release and full bloom at 1.60 sec after release. Aircraft position data were used initially to determine the position and velocity at release. Minor adjustments to these values were made in order to improve the match between the observed and computed trajectories during the time from release to the beginning of parachute deployment.

The ground level at the test site is approximately 5330 ft above mean sea level. Cinetheodolites were used to track the aircraft and store to obtain spatial coordinates. Mitchell cameras were used to determine event times.

An aerodynamic drag coefficient as a function of time was used in the computation. After several attempts were made to improve the match between the observed and computed position data, a drag coefficient was obtained that provided an excellent match in trajectory arc length over the entire trajectory. This match in arc length was based on the assumption that the aerodynamic drag force is always parallel and in the opposite direction to the true airspeed of the missile.

There were, however, noticeable differences in range and deflection at intermediate and terminal points that could not be eliminated by adjusting the initial release conditions. The differences suggested the possibility that there were forces normal to the velocity acting on the store. The following paragraph substantiates the possibility.

"The great majority of canopy designs of all types generate unsymmetrical aerodynamic forces, the force vector does not remain steadily tangent to the flight

patch and will create oscillation inducing moments if a stable glide is not possible."2

In order to compensate for the differences in range and deflection without affecting the match in arc length, two additional accelerations were included in the equations of motion. These accelerations were perpendicular to the velocity of the store; one was in a vertical plane and the other in a horizontal plane (see Appendix C) and were made proportional to the dynamic air pressure beginning at 1.3 sec after release. Proportionality constants were determined by trial and error that reduced the range and deflection differences at both intermediate and terminal points to values that were considered insignificant without affecting the match in arc length.

The acceleration, G, was computed for every time line by dividing the vector sum of the components of acceleration by the acceleration of gravity.

RESULTS

Graphs of the aerodynamic drag, CD, and G profile obtained with the procedure described in this report are presented in Figures 2 and 3. The same values are also presented in Figures 4 and 5 along with the values obtained by using two different smoothing techniques. In these figures, the curves labeled A were obtained by smoothing the observed position data with a constrained low pass CHI digital filter. The curves labeled B were obtained by fitting a moving arc of 11 data points with a least-squares second-degree polynominal evaluated at the midpoint. The moving arc procedure is described in Reference 3. The curves labeled C in Figures 4 and 5 are the same curves that are shown in Figures 2 and 3 but drawn to different scales.

It may be noted that the aerodynamic drag shown in Figure 2 " at was computed using numerical integration contains spikes that do not appear in the drags computed using smoothing techniques. The spikes indicate that the parachute partially collapsed twice before it reached full bloom. This conclusion is supported

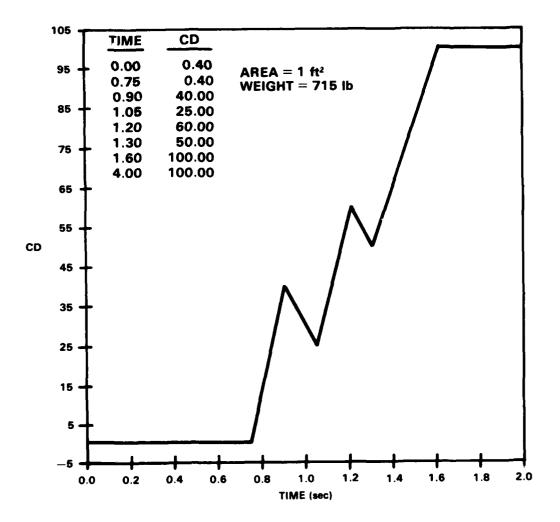

FIGURE 2. DRAG COEFFICIENT VERSUS TIME

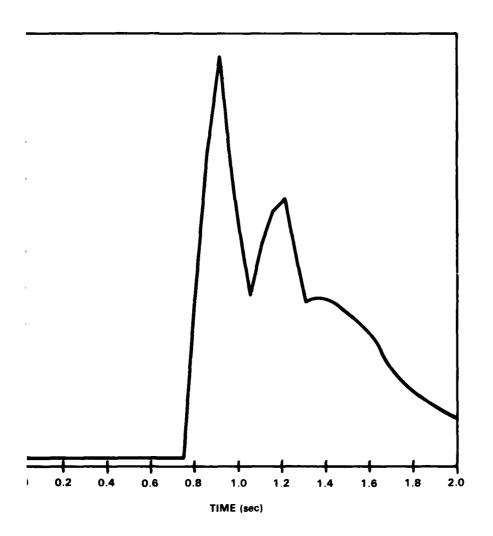

FIGURE 3. G VERSUS TIME

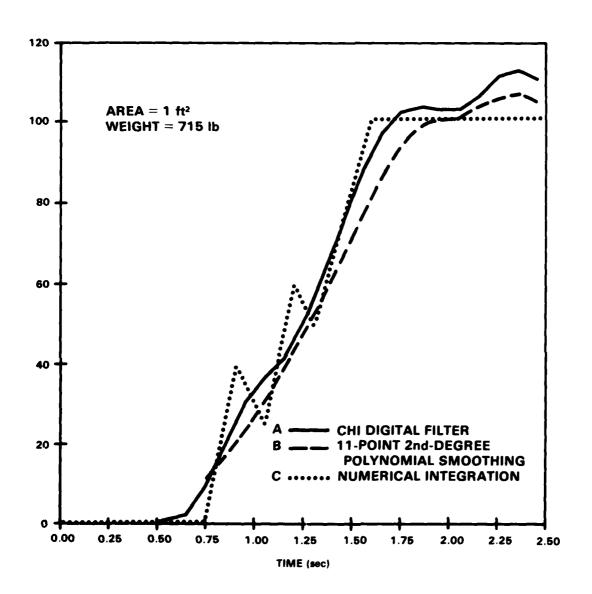

FIGURE 4. DRAG COEFFICIENT VERSUS TIME

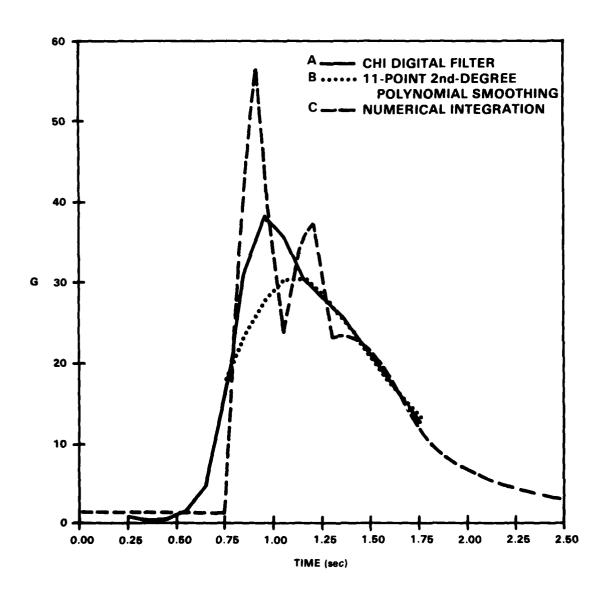

FIGURE 5. G VERSUS TIME

by the fact this parachute took approximately 0.5 sec longer than normal to reach full bloom.

The spikes in the aerodynamic drag are reflected in the G schedule that has a considerably larger maximum G than was obtained by either one of the methods that involves a smoothing technique.

The method of using numerical integration to determine the aerodynamic drag has another distinct advantage when the store is subjected to normal forces. Small forces in this category may be identified and evaluated, which most likely would go undetected, if a smoothing technique were used. The accelerations perpendicular to the velocity used in the sample trajectory shift the terminal point of the trajectory 16 and 36 ft in range and deflection, respectively, and also improve the match between the observed and computed position data at intermediate points. It was possible by using the method presented in this report to obtain an excellent match in all three position coordinates throughout the entire sample trajectory.

Four sets of differences between the computed and observed position data are given in Appendix D for every time line of the computed trajectory. The first set was obtained by comparing the observed position data with a trajectory that was computed using the drag shown in Figure 2 and the accelerations described in Appendix C. The second set is differences obtained by using the same drag but without the accelerations. The third set was obtained by using the drag labeled A in Figure 4. This drag was computed by smoothing the data with a constrained low-pass CHI digital filter. The fourth set was obtained by using the drag labeled B in Figure 4 that was computed by smoothing the data with a second-degree polynomial fit to a moving arc consisting of 11 data points. The differences in time of flight, range, deflection, and arc length at the terminal point and the maximum G are summarized in Table 1.

TABLE 1. DIFFERENCES BETWEEN OBSERVED AND COMPUTED TRAJECTORIES

Set	Time of Flight (sec)	Range (ft)	Deflection (ft)	Arc Length (ft)	Max G
1	-0.025	-2.480	-1.386	1.846	56.6
2	-0.183	-15.986	35.594	1.915	56.6
3	-0.237	-5.403	35.571	13.412	36.8
4	-0.158	-45.001	35.291	-27.865	30.6

The differences are the observed minus the computed values.

The maximum G in Set 3 is 66% of the value in Sets 1 and 2. The maximum G in Set 4 is 56% of the value in Sets 1 and 2. Set 4 has the largest differences in range, deflection, and arc length. A noticeable improvement in the differences throughout the trajectory, as well as the terminal point, was made by introducing the accelerations perpendicular to the velocity vector. There is only one difference in the X, Y, and Z position coordinates in Set 1 in the entire trajectory that exceeds 4 ft and a majority of the differences is less than 2 ft. The differences in arc length are even less. Only four of the differences in arc length exceed 2 ft and the maximum is 2.65 ft.

The unsmoothed position data are presented in Appendix E. The trajectory data computed using the aerodynamic drag shown in Figure 2 and the acceleration described in Appendix C are presented in Appendix F.

This procedure of matching unsmoothed observed position data with computed position data can also be used to identify and correct erroneous observed event times such as parachute deployment schedules, rocket motor ignition and burnout, and booster motor separation, etc. It can also be used to derive rocket—thrust curves, separation effects due to launch disturbances, bomb rack ejection velocity, and a host of other parameters encountered in trajectory analysis. However, this procedure, in some cases, may be laborious and require previous knowledge of certain parameters in order to isolate others. The accuracy of the results obtained are also highly dependent upon the accuracy of the unsmoothed position data. In summary, if the analyst is working with a weapon that has no inflight events or is interested only in a set of parameters that will predict the trajectory impact point, then a procedure that employs smoothing may produce satisfactory results with minimum effort. Conversely, if the weapon is subject to events that produce accelerations and the analyst is interested in accurate estimates of these events, then the use of the trajectory matching technique should be attempted.

CONCLUSIONS

The procedure described in this report makes it possible to determine the aerodynamic drag and G profile of a missile that has large perturbations or very high decelerations occurring in a very short time without smoothing the spatial coordinates.

The accelerations (decelerations) that result from perturbations in a trajectory may be determined with much greater accuracy using numerical integration to match observed position data than can be obtained with any of the existing smoothing techniques.

This procedure may be used to pinpoint phenomena that might otherwise escape identification, if one of the available smoothing techniques were used. Many of the procedures frequently used employ smoothing techniques that reduce the peaks and valleys in the data that may actually belong there. This procedure avoids that problem by using unsmoothed data.

Smoothing techniques may be used to a good advantage to reduce the noise in data where there are no large or abrupt changes in the velocity or acceleration but will invariably reduce any sudden perturbations that may belong in the data.

Recording accelerometers are often used to monitor flight gear and fuze performance during drop tests. The high costs, additional instrumentation requirements, and sometimes low success rate of using recording accelerometers make the method presented in this report an attractive alternate or backup. The procedure provides for the reduction of G data without requiring any modifications or instrumentation of the store.

APPENDIX A SMOOTHING TECHNIQUES

SMOOTHING TECHNIQUES

The decision of selecting an appropriate method for smoothing data may not be an easy task. It is important to select a function that fits the true value of the data. There may be a temptation to increase the degree of a polynomial used in a least-squares fit, in order to reduce the sum of the squares of the residuals. This could be carried to the point where one was merely fitting the noise. Increasing the degree of a polynomial beyond that which fits the true value of the data should be avoided if possible. Unless some information is available about the nature of the data, it may be extremely difficult to determine what function fits the true value when the data contains noise. In the event that this information is available and an appropriate function has been selected, the next decision is the number of data points to be used in the fit. What frequently happens in actual practice is that the function selected for smoothing is only a good approximation of the true value over a short segment of the data. Increasing the length of the segment by using more data points may actually degrade the results. It is desirable to use a function that is a good approximation over a large enough segment of data that the noise level within the fit will have a random distribution. (It is quite possible to encounter noise that does not have a random distribution that further complicates the problem.)

Excellent results can usually be obtained by using a second-degree polynominal to smooth trajectory data that contain moderate levels of acceleration and noise. Smoothing data with high levels of acceleration as in the case of a weapon that has a parachute to increase the air resistance is frequently difficult to perform regardless of the procedure used. The quality of the data may also be an important factor; it may be so poor that no attempt should be made to smooth it.

Two excellent sources of information on smoothing techniques are References A-1 and A-2.

There is a diversity of opinion among people who process and analyze data concerning the many numerical methods used in smoothing measured quantities and in the retrieval of information from erroneous observations. The literature on this subject is voluminous. Of the many methods, all use assumptions of the functional form of the basic data trend or statistical properties or origin of errors in an effort to obtain a numerical process which will, within the imposed constraints, improve the data by minimizing errors. The choice of a technique must depend upon the objective sought. Some investigation of a given technique's potential in describing the data must be made. A-1

The concept of smoothing is based on the fact that physical events occur at continuously varying rates in nature. In ballistic missiles, while moments of apparent discontinuity in a trajectory do occur during periods of large accelerations (i.e., control changes, thrust initiation or termination, reentry, etc.), the trajectory basically is defined by a continuous function. At this point it should be emphatically stated that smoothing does not improve the accuracy of the observations; it merely presents the most likely performance of the observed phenomena based on the recorded observations. It may deprecate the quality of the data, if it removes actual perturbations in the observed function. There are three currently used techniques of smoothing: use of orthogonal polynomials (applied to trajectory data to get an analytical expression for the actual trajectory), differencing equations, and moving averages. The most commonly used of the three is the moving-average technique. A-2

In spite of the fact that the above restrictions on the use of smoothing routines are frequently ignored, fairly good estimates of position, velocity, and acceleration are produced using standard smoothing if the universe of calculated data is sufficiently large.

One final comment should be made regarding the use of standard smoothing routines. Mathematical models employed do not incorporate known external information about the observed phenomena. $^{\rm A-2}$

The above quotation is preceded by a lengthy discussion of a number of restrictions.

Note: The observed velocity of the bomb was input as zero; consequently, the difference in velocity, VD, has the same magnitude as the computed velocity but opposite in sign.

CONTINUO

Set 2 shows the differences between observed position data and data computed using the aerodynamic drag labeled C in Figure 4 and without the accelerations perpendicular to the velocity vector as described in Appendix C.

Note: The observed velocity of the bomb was input as zero; consequently, the difference in velocity, VD, has the same magnitude as the computed velocity but opposite in sign.

Set 3 shows the differences between observed position data and data computed using the aerodynamic drag (labeled A in Figure 4) obtained by smoothing the data with a constrained low-pass CHI digital filter and without the accelerations perpendicular to the velocity vector as described in Appendix C.

Note: The observed velocity of the bomb was input as zero; consequently, the difference in velocity, VD, has the same magnitude as the computed velocity but opposite in sign.

SET 4

Set 4 shows the differences between observed position data and data computed using the aerodynamic drag (labeled B in Figure 4) obtained by smoothing the data with a second-degree polynomial fit to a 11-point moving arc evaluated at the midpoint.

APPENDIX G GLOSSARY OF DATA-REDUCTION TERMS

GLOSSARY OF DATA-REDUCTION TERMS

ALTITUDE altitude above mean sea level (ft)

AOF angle of fall (deg)

ARC arc length of trajectory (ft)

ARD observed minus computed arc length (ft)

CD aerodynamic drag coefficient (dimensionless)

CDS product of the drag coefficient, CD, and the cross-sectional frontal

area (ft²)

DD observed minus computed deflection at the terminal point (ft)

DENSITY air density (lb/ft³)

DR observed minus computed range at the terminal point (ft)

DRIFT drift of a projectile due to spin (ft)

pr observed minus computed range at the terminal point (ft)

E* component of wind blowing east (ft/sec)

G total acceleration divided by the acceleration of gravity

MACH NO Mach number

N* component of wind blowing north (ft/sec)

SF scale factor for aerodynamic drag

T time from release (sec)

TEMP air temperature (Kelvin)

THRUST thrust of a rocket motor (1b)

velocity of a missile with respect to an earth fixed origin (ft/sec)

VA true airspeed (ft/sec)

VD observed minus computed velocity (ft/sec)

WT weight of missile (lb)

wx x component of wind (ft/sec)

wy y component of wind (ft/sec)

x coordinate of position (ft)

x* x component of velocity (ft/sec)

X**	x component of acceleration (ft/sec ²)
XD	observed minus computed x coordinate (ft)
Y	y coordinate of position (ft)
Y*	y component of acceleration (ft/sec)
Y**	y component of acceleration (ft/sec ²)
YD	observed minus computed y coordinate (ft)
2	z coordinate of position (ft)
Z*	z component of velocity (ft/sec)
Z**	z component of acceleration (ft/sec ²)
ZD	observed minus computed z coordinate (ft)
ZSL	altitude above mean sea level (ft)
